# Chapter 3: Functions

# Contents

- Functions
- Specifications
- Keywords: `return` vs `print`
- Variable scope
- Default values
- Lambda functions
- Recursion

# Opening Problem

- Find the sum of integers from 1 to 10, from 20 to 37, and from 35 to 49, respectively.

# Problem

```
sum = 0
for i in range(1, 10):
    sum += i
print("Sum from 1 to 10 is", sum)
```

```
sum = 0
for i in range(20, 37):
    sum += i
print("Sum from 20 to 37 is", sum)
```

```
sum = 0
for i in range(35, 49):
    sum += i
print("Sum from 35 to 49 is", sum)
```

# Problem

```
sum = 0
for i in range(1, 10):
    sum += i
print("Sum from 1 to 10 is", sum)
```

```
sum = 0
for i in range(20, 37):
    sum += i
print("Sum from 20 to 37 is", sum)
```

```
sum = 0
for i in range(35, 49):
    sum += i
print("Sum from 35 to 49 is", sum)
```

# Solution

```
def sum(i1, i2):  
    result = 0  
    for i in range(i1, i2):  
        result += i  
    return result
```

```
def main():  
    print("Sum from 1 to 10 is", sum(1, 10))  
    print("Sum from 20 to 37 is", sum(20, 37))  
    print("Sum from 35 to 49 is", sum(35, 49))
```

```
main() # Call the main function
```

# Defining Functions

- A function is a collection of statements that are grouped together to perform an operation. In Python a function is some reusable code that takes arguments(s) as input does some computation and then returns a result or results
- Function characteristics:
  - has a **name**
  - has **parameters** (0 or more)
  - has a **docstring** (optional but recommended)
  - has a **body**
  - **returns** something

# Python Functions

- There are two kinds of functions in Python
- Built-in functions that are provided as part of Python - `input()`, `type()`, `float()`, `max()`, `min()`, `int()`, `str()`, ...
- Functions (user defined) that we define ourselves and then use
- We treat the built-in function names like reserved words (i.e. we avoid them as variable names)

# Built-in functions

## Type conversions

- can **convert object of one type to another**
- When you put an integer and floating point in an expression the integer is implicitly converted to a float
- You can control this with the built in functions `int()` and `float()`

```
>>> print (float(99) / 100)
0.99
>>> i = 42
>>> type(i)
<class 'int'>
>>> f = float(i)
>>> print (f)
42.0
>>> type(f)
<class 'float'>
>>> print (1 + 2 * float(3) - 5)
2.0
>>>
```

# Built-in functions

## String Conversions

- You can also use `int()` and `float()` to convert between strings and integers
- You will get an error if the string does not contain numeric characters

```
>>> sval = '123'
>>> type(sval)
<class 'str'>
>>> print (sval + 1)
Traceback (most recent call last):
  File "<pyshell#10>", line 1, in <module>
    print (sval + 1)
TypeError: can only concatenate str (not "int") to str
>>> ival = int(sval)
>>> type(ival)
<class 'int'>
>>> print (ival + 1)
124
>>> nsv = 'hello bob'
>>> niv = int(nsv)
Traceback (most recent call last):
  File "<pyshell#9>", line 1, in <module>
    niv = int(nsv)
ValueError: invalid literal for int() with
base 10: 'hello bob'
```

# User-defined functions

- We create a new function using the def keyword followed by the function name, optional parameters in parenthesis, and then we add a colon.
- We indent the body of the function
- This defines the function but does not execute the body of the function

```
def print_lyrics():  
    print("I'm a lumberjack, and I'm okay.")  
    print('I sleep all night and I work all day.')
```

# How to write a function

**keyword** **name** **parameters or arguments** **specification, docstring**

```
def is_even( i ) :  
    """  
    Input: i, a positive int  
    Returns True if i is even, otherwise False  
    """  
    print("inside is_even")  
    return i%2 == 0  
  
is_even(3)
```

**body**

later in the code, you call the function using its name and values for parameters

# In the function body

```
def is_even( i ):
```

```
    """
```

```
    Input: i, a positive int
```

```
    Returns True if i is even, otherwise False
```

```
    """
```

```
    print("inside is_even")
```

```
    return i%2 == 0
```

keyword

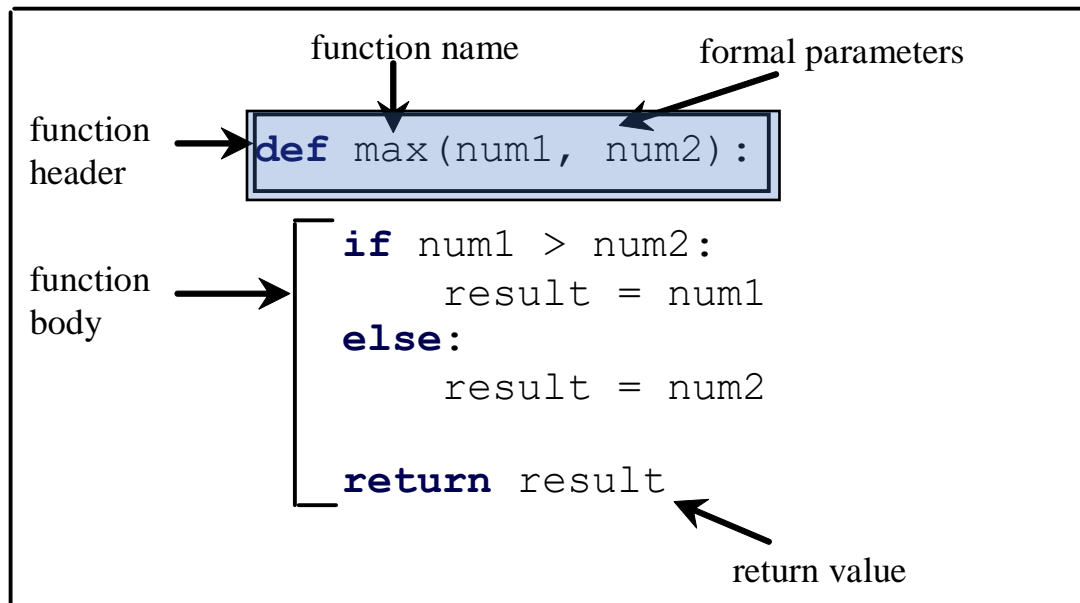

expression to  
evaluate and return

run some  
commands

# Function Header

A function contains a header and body. The header begins with the **def** keyword, followed by function's name and parameters, followed by a colon.

Define a function

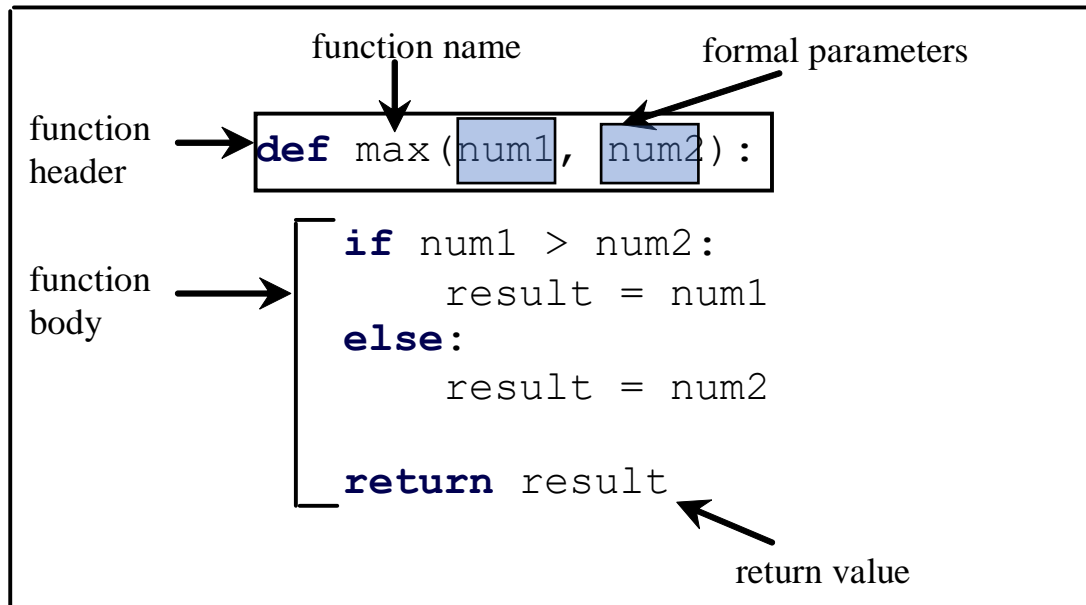

Invoke a function

# Formal Parameters

- The variables defined in the function header are known as *formal parameters*.
- A *formal parameter* is a variable which we use in the function definition that is a “handle” that allows the code in the function to access the arguments for a particular function invocation.

Define a function

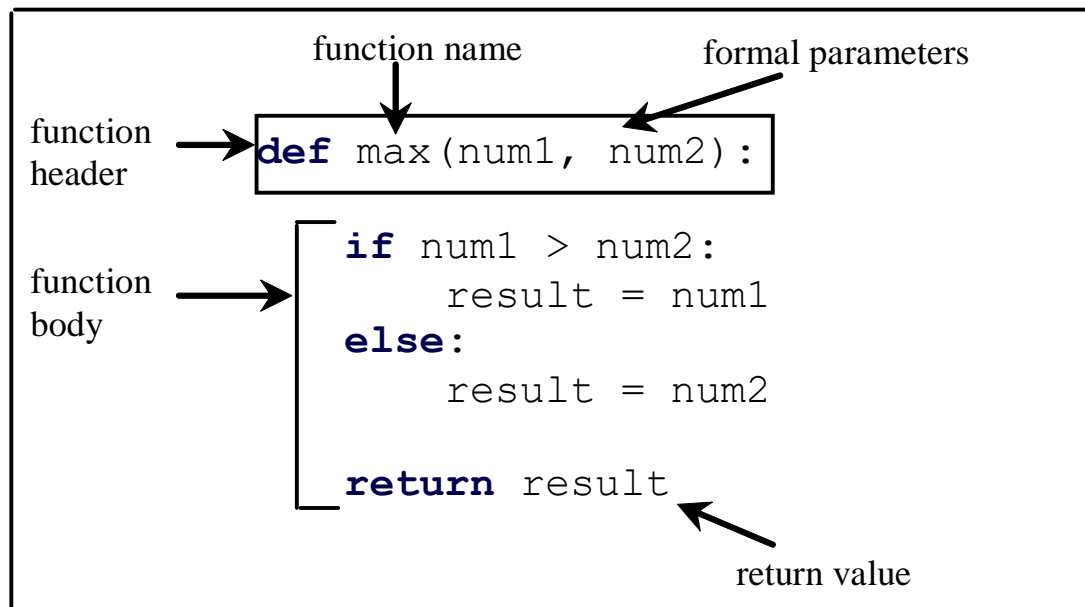

Invoke a function

# Actual Parameters

When a function is invoked, you pass a value to the parameter. This value is referred to as *actual parameter or argument*.

Define a function

Invoke a function

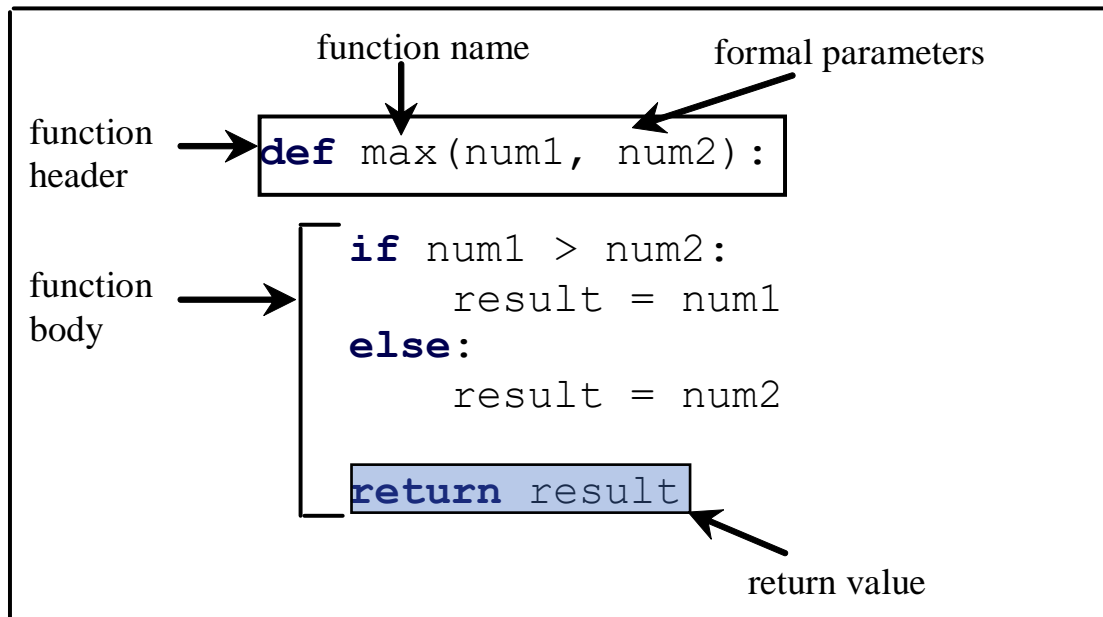

# Arguments

- An argument is a value we pass into the function as its input when we call the function
- We use arguments so we can direct the function to do different kinds of work when we call it at different times
- We put the arguments in parenthesis after the name of the function

# Return Value

Often a function will take its arguments, do some computation and return a value to be used as the value of the function call in the calling expression. The return keyword is used for this.

Define a function

Invoke a function

# Return Value

- A “fruitful” function is one that produces a result (or a return value)
- The return statement ends the function execution and “sends back” the result of the function

```
def greet(lang):  
    if lang == 'es':  
        return('Hola ')  
    elif lang == 'fr':  
        return('Bonjour ')  
    else:  
        return('Hello ')
```

```
print(greet('en'), 'Glenn')  
Hello Glenn
```

```
print(greet('es'), 'Sally')  
Hola Sally
```

```
print(greet('fr'), 'Michael')  
Bonjour Michael
```

# Void Functions

- When a function does not return a value, we call it a "void" function
- Void functions are "not fruitful"

# Multiple Parameters / Arguments

- We can define more than one parameter in the function definition
- We simply add more arguments when we call the function
- We match the number and order of arguments and parameters

```
def addtwo(a, b):  
    added = a + b  
    return added
```

```
x = addtwo(3, 5)  
print(x)  
8
```

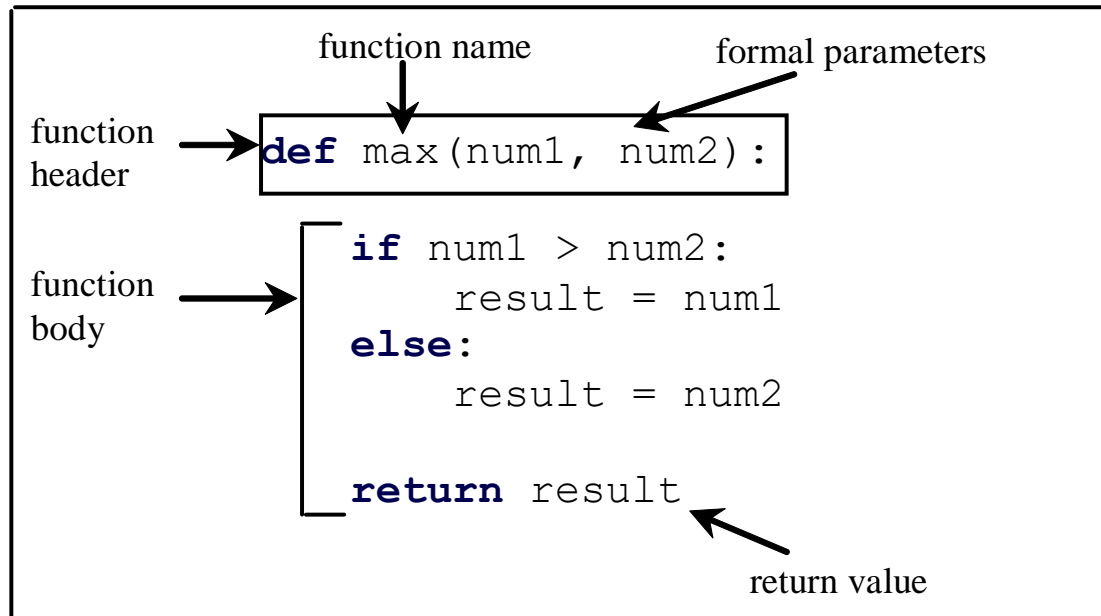

# Definitions and Uses

- Once we have defined a function, we can call (or invoke) it as many times as we like
- This is the store and reuse pattern

# Calling Functions

- Testing the max function
- This program demonstrates calling a function max to return the largest of the int values

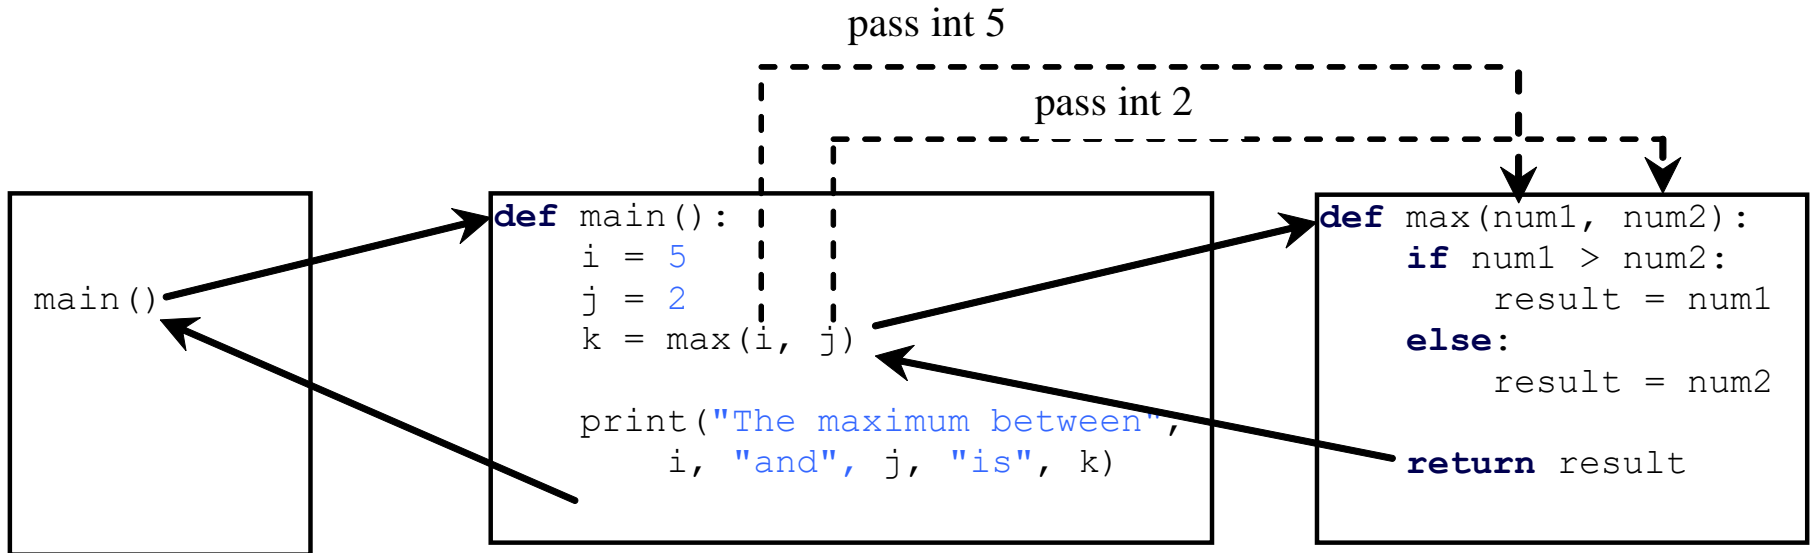

Define a function

Invoke a function

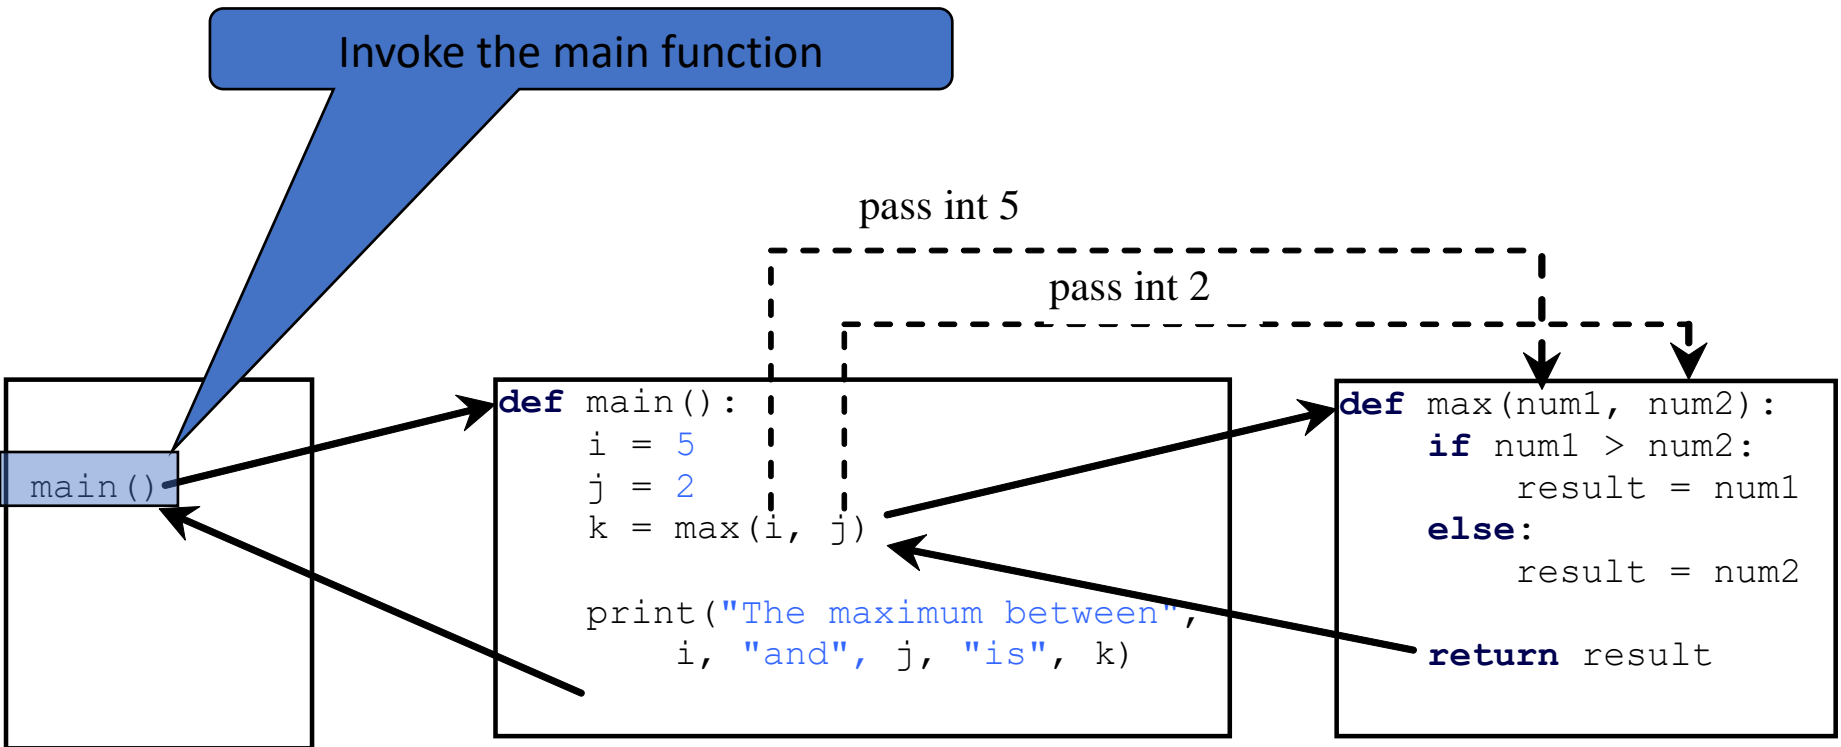

# Calling Functions, cont.

# Pass by value and pass by reference

- In pass-by-value, the function receives a copy of the argument objects passed to it by the caller, stored in a new location in memory.
- You pass values of parameter to the function, if any kind of change done to those parameters inside the function ,those changes not reflected back in your actual parameters.
- In pass-by-reference, the function receives reference to the argument objects passed to it by the caller, both pointing to the same memory location.
- You pass reference of parameters to your function, if any changes made to those parameters inside function those changes are get reflected back to your actual parameters.
- In Python, neither of these two concepts are applicable, rather the **values are sent to functions by means of object reference.**

# Pass-by-object-reference

- In Python, (almost) everything is an object. What we commonly refer to as “variables” in Python are more properly called names. Likewise, “assignment” is really the binding of a name to an object. Each binding has a scope that defines its visibility, usually the block in which the name originates.
- In Python, values are passed to function by object reference.
- if object is immutable (not modifiable) then the modified value is not available outside the function.
- if object is mutable (modifiable) then modified value is available outside the function.

# Pass-by-object-reference

- **Immutable objects:** int, float, complex, string, tuple, frozen set, bytes.
- **Mutable objects:** list, dict, set, byte array

```
def val(x):
```

```
    x = 15
```

```
    print(x, id(x))
```

```
x = 10
```

```
val(x)
```

```
print(x, id(x))
```

x = 10

x  
10  
23425

x = 15

x  
15  
76525

A new object is created in the memory because integer objects are immutable (not modifiable).

```
def val(lst):
```

```
    lst.append(4)
```

```
    print(lst, id(lst))
```

```
lst = [1, 2, 3]
```

```
print(lst, id(lst))
```

```
val(lst)
```

lst = [1,2,3]

lst  
1,2,3,4  
76345

lst = [1,2,3,4]

lst

A new object is not created in the memory because list objects are mutable (modifiable). It simply add new element to the same object.

# Modules and the import statement

- A program can load a module file by using the import statement
- Use the name of the module
- Functions and variables names in the module must be qualified with the module name. e.g. math.pi

```
import math
radius = 2.0
area = math.pi * (radius ** 2)
12.5663706144
```

```
math.log(5)
1.6094379124341003
```

```
import sys
sys.exit()
```

# Variable scope

- **formal parameter** gets bound to the value of **actual parameter** when function is called
- new **scope/frame/environment** created when enter a function
- **scope** is mapping of names to objects

```
def f( x ) :  
    x = x + 1  
    print('in f(x): x =', x)  
    return x
```

*formal  
parameter*

*Function  
definition*

```
x = 3
```

```
z = f( x )
```

*actual  
parameter*

*Main program code*  
\* initializes a variable x  
\* makes a function call f(x)  
\* assigns return of function to variable z

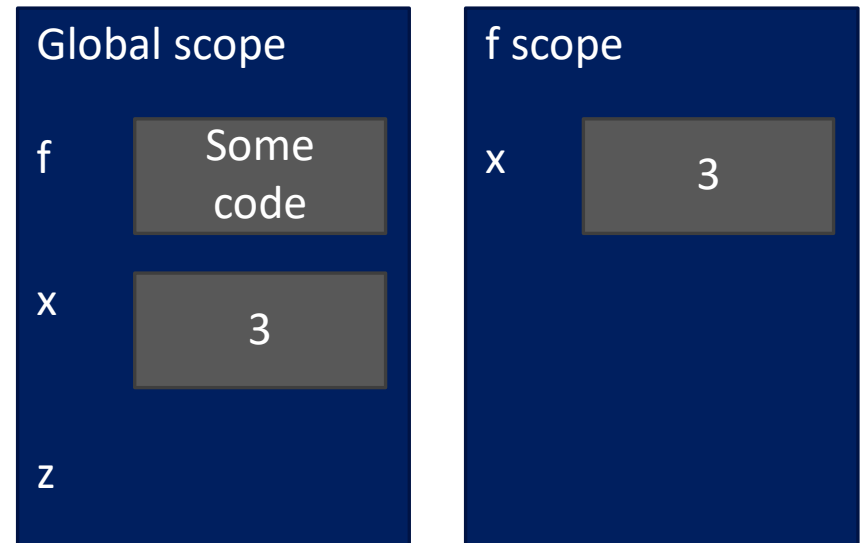

# Variable scope

```
def f( x ) :  
    x = x + 1  
    print('in f(x): x =', x)  
    return x
```

```
x = 3
```

```
z = f( x )
```

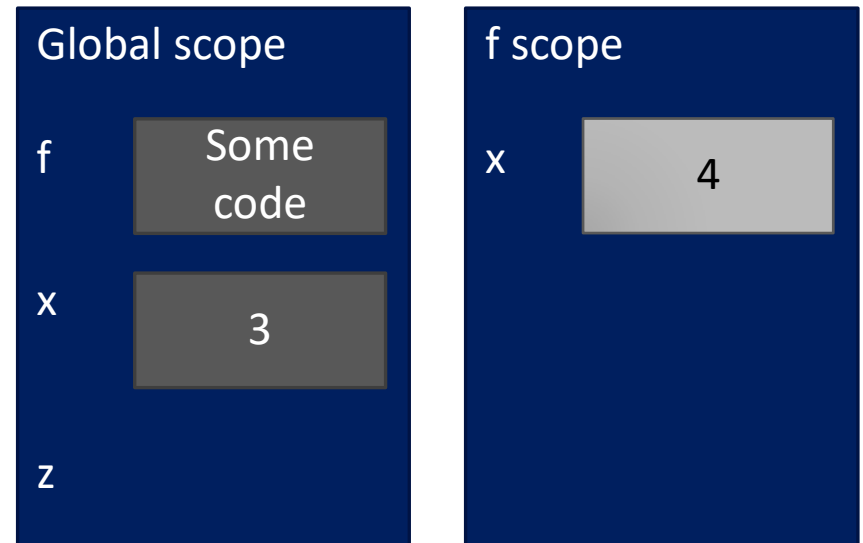

# Variable scope

```
def f( x ) :  
    x = x + 1  
    print('in f(x): x =', x)  
    return x
```

```
x = 3
```

```
z = f( x )
```

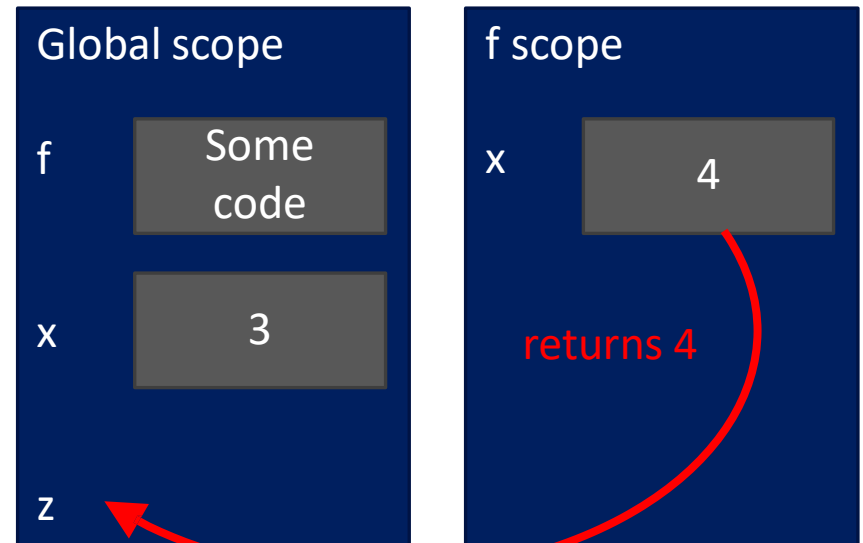

# Variable scope

```
def f( x ):  
    x = x + 1  
    print('in f(x): x =', x)  
    return x
```

```
x = 3
```

```
z = f( x )
```

# Variable scope

```
def f( x ) :  
    x = x + 1  
    print('in f(x): x =', x)  
    return x
```

```
x = 3  
z = f( x )
```

# ONE WARNING IF NO return STATEMENT

```
def is_even( i ):  
    """  
    Input: i, a positive int  
    Does not return anything  
    """
```

`i%2 == 0`

*without a return  
statement*

- Python returns the value **None, if no return given**
- represents the absence of a value

# return vs. print

- return only has meaning **inside** a function
  - only **one** return executed inside a function
  - code inside function but after return statement not executed
  - has a value associated with it, **given to function caller**
- print can be used outside functions
  - can execute many print statements inside a function
  - code inside function can be executed after a print statement
  - has a value associated with it, outputted to the console

# Functions as arguments

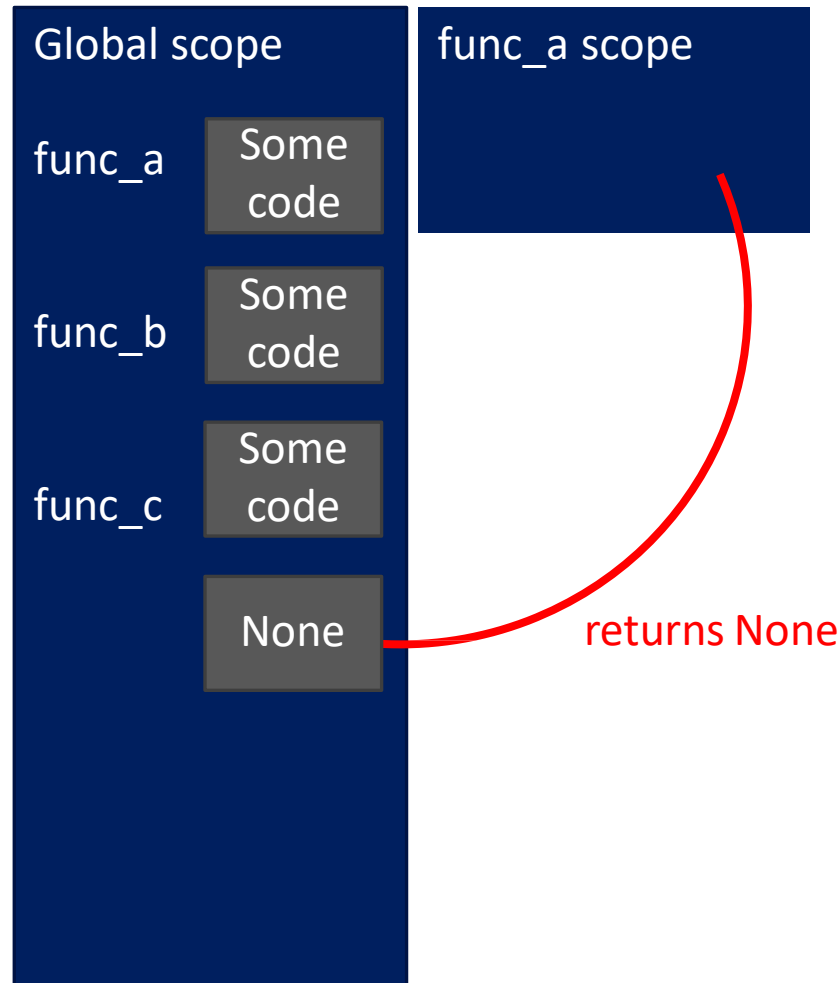

- arguments can take on any type, even functions

```
def func_a():  
    print('inside func_a')  
  
def func_b(y):  
    print('inside func_b')  
    return y  
  
def func_c(z):  
    print('inside func_c')  
    return z()  
  
print(func_a())  
print(5 + func_b(2))  
print(func_c(func_a))
```

*call func\_a, takes no parameters*  
*call func\_b, takes one parameter*  
*call func\_c, takes one parameter, another function*

# Functions as arguments

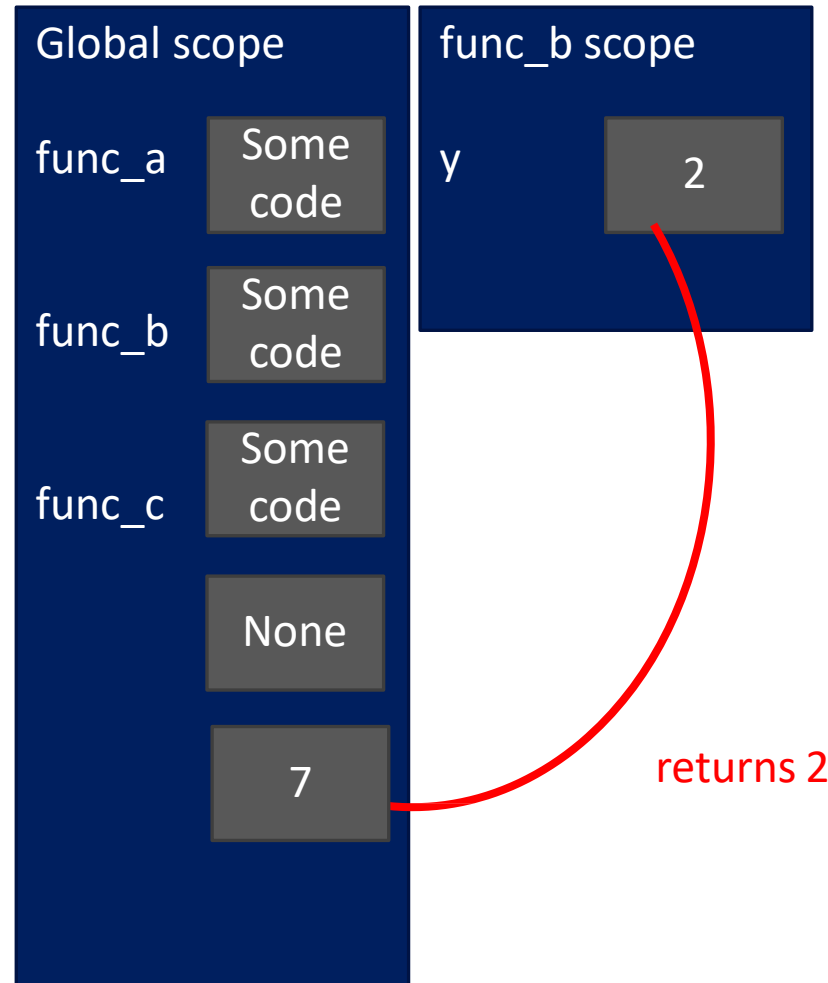

```
def func_a():  
    print('inside func_a')  
def func_b(y):  
    print('inside func_b')  
    return y  
def func_c(z):  
    print('inside func_c')  
    return z()  
  
print(func_a())  
print(5 + func_b(2))  
print(func_c(func_a))
```

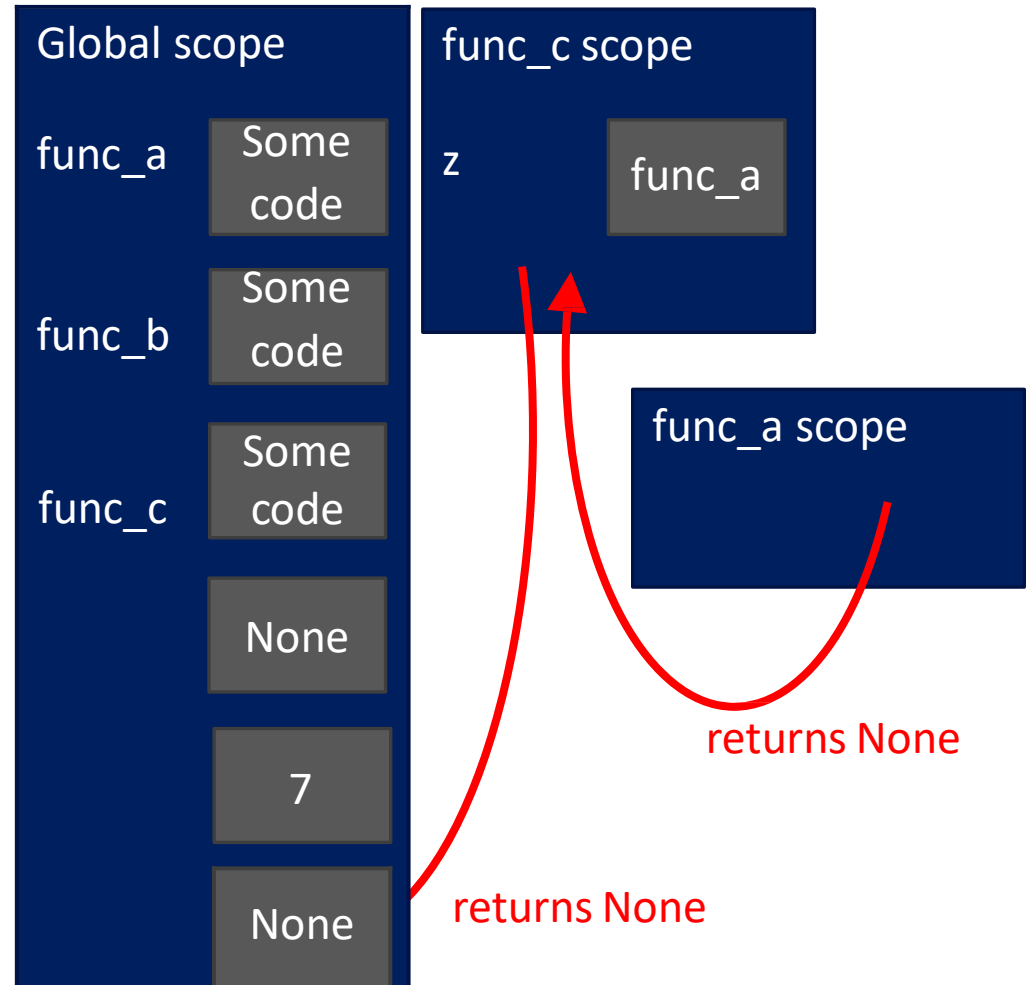

# Functions as arguments

```
def func_a():  
    print('inside func_a')  
  
def func_b(y):  
    print('inside func_b')  
    return y  
  
def func_c(z):  
    print('inside func_c')  
    return z()  
  
print(func_a())  
print(5 + func_b(2))  
print(func_c(func_a))
```

# Functions as arguments

```
def func_a():  
    print('inside func_a')  
  
def func_b(y):  
    print('inside func_b')  
    return y  
  
def func_c(z):  
    print('inside func_c')  
    return z()  
  
print(func_a())  
print(5 + func_b(2))  
print(func_c(func_a))
```

# Scope example

- inside a function, can access a variable defined outside
- inside a function, cannot modify a variable defined outside -- can using global variables, but frowned upon

```
def f(y):  
    x = 1  
    x += 1  
    print(x)
```

*x is re-defined  
in scope of f*

```
x = 5  
f(x)  
print(x)
```

*different x  
objects*

```
def g(y):  
    print(x)  
    print(x + 1)
```

*x from  
outside g*

```
x = 5  
g(x)  
print(x)
```

*x inside g is picked up  
from scope that called  
function g*

```
def h(y):  
    x += 1
```

```
x = 5  
h(x)  
print(x)
```

*UnboundLocalError: local variable  
'x' referenced before assignment*

# Scope example

- inside a function, can access a variable defined outside
- inside a function, cannot modify a variable defined outside -- can using global variables, but frowned upon

```
def f(y):  
    x = 1  
    x += 1  
    print(x)
```

```
x = 5
```

```
f(x)
```

```
print(x)
```

```
def g(y):  
    print(x)
```

```
x = 5
```

```
g(x)
```

```
print(x)
```

```
def h(y):  
    x += 1
```

```
x = 5
```

```
h(x)
```

```
print(x)
```

x from  
global/main  
program scope

# Harder scope example

# Scope details

```
def g(x):  
    def h():  
        x = 'abc'  
    x = x + 1  
    print('g: x =', x)  
    h()  
    return x
```

*Some code*

```
x = 3  
z = g(x)
```

# Scope details

```
def g(x):  
    def h():  
        x = 'abc'  
    x = x + 1  
    print('g: x =', x)  
    h()  
    return x
```

```
x = 3  
z = g(x)
```

# Scope details

```
def g(x):  
    def h():  
        x = 'abc'  
    x = x + 1  
    print('g: x =', x)  
    h()  
    return x
```

```
x = 3  
z = g(x)
```

# Scope details

```
def g(x):  
    def h():  
        x = 'abc'  
    x = x + 1  
    print('g: x =', x)  
    h()  
    return x
```

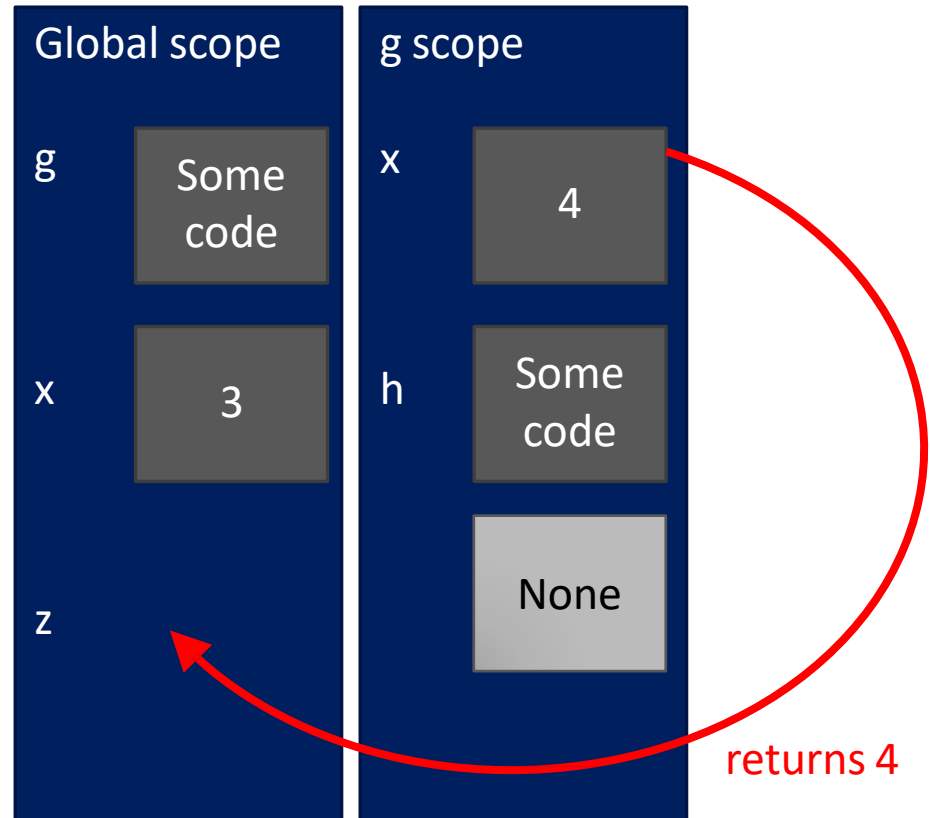

```
x = 3  
z = g(x)
```

# Scope details

```
def g(x):  
    def h():  
        x = 'abc'  
    x = x + 1  
    print('g: x =', x)  
    h()  
    return x
```

```
x = 3  
z = g(x)
```

# Scope details

```
def g(x):  
    def h():  
        x = 'abc'  
    x = x + 1  
    print('g: x =', x)  
    h()  
    return x
```

```
x = 3  
z = g(x)
```

# Default Parameter Value

- If we call the function without argument, it uses the default value

```
def my_function(country = "Vietnam"):  
    print("I am from " + country)
```

```
my_function("Sweden")  
my_function("India")  
my_function()  
my_function("Brazil")
```

# Default Parameter Value

- A function can have multiple parameters with default values. Parameters with default values need to be grouped into the last (or unique) parameters of a function. When calling a function with multiple parameters with default values, we can only omit the parameters in the order from right to left and must drop them consecutively.

```
def func(a, b = 3, c = 5):  
    return a + b + c  
  
print(func(1), func(1, 5), func(1, 5, 9))
```

# Lambda function

- A lambda function is a small anonymous function.
- In contrast to a normal function, a Python lambda function is a single expression. Although, in the body of a lambda, you can spread the expression over several lines using parentheses or a multiline string, it remains a single expression

- Syntax:

```
lambda arguments : expression
```

# Lambda function

```
x = lambda a : a + 10  
print(x(5))
```

```
x = lambda a, b : a * b  
print(x(5, 6))
```

```
x = lambda a, b, c : a + b + c  
print(x(5, 6, 2))
```

# Lambda function

```
def myfunc(n):  
    return lambda a : a * n
```

```
mydoubler = myfunc(2)  
mytripler = myfunc(3)
```

```
print(mydoubler(11))  
print(mytripler(11))
```

# Lambda function

```
(lambda x: x + 1)(2)
```

```
(lambda x, y: x + y)(2, 3)
```

```
>>> high_ord_func = lambda x, func: x + func(x)
```

```
>>> high_ord_func(2, lambda x: x * x)
```

6

```
>>> high_ord_func(2, lambda x: x + 3)
```

7

HA NOI UNIVERSITY OF SCIENCE AND TECHNOLOGY  
SCHOOL OF INFORMATION AND COMMUNICATION TECHNOLOGY

# Recursion

# WHAT IS RECURSION?

- Algorithmically: a way to design solutions to problems by **divide-and-conquer** or **decrease-and-conquer**
  - reduce a problem to simpler versions of the same problem
- Semantically: a programming technique where a
  - **function calls itself**
    - in programming, goal is to NOT have infinite recursion
      - must have **1 or more base cases** that are easy to solve
      - must solve the same problem on **some other input** with the goal of simplifying the larger problem input

# ITERATIVE ALGORITHMS SO FAR

- looping constructs (`while` and `for` loops) lead to **iterative** algorithms
- can capture computation in a set of **state variables** that update on each iteration through loop

# MULTIPLICATION – ITERATIVE SOLUTION

- “multiply  $a * b$ ” is equivalent to “add  $a$  to itself  $b$  times”

- capture **state** by

- an **iteration** number ( $i$ ) starts at  $b$   
 $i \leftarrow i-1$  and stop when 0
- a current **value of computation** (result)  
 $\text{result} \leftarrow \text{result} + a$

```
def mult_iter(a, b):  
    result = 0  
    while b > 0:  
        result += a  
        b -= 1  
    return result
```

iteration  
current value of computation,  
a running sum  
current value of iteration variable

# MULTIPLICATION – RECURSIVE SOLUTION

- recursive step
  - think how to reduce problem to a simpler/ smaller version of same problem
- base case
  - keep reducing problem until reach a simple case that can be solved directly
  - when  $b = 1$ ,  $a*b = a$

$$\begin{aligned} a*b &= \underbrace{a + a + a + a + \dots + a}_{b \text{ times}} \\ &= a + \underbrace{a + a + a + \dots + a}_{b-1 \text{ times}} \\ &= a + \boxed{a * (b-1)} \end{aligned}$$

recursive reduction

```
def mult(a, b):
```

```
    if b == 1:
        return a
```

```
    else:
        return a + mult(a, b-1)
```

# FACTORIAL

$$n! = n * (n-1) * (n-2) * (n-3) * \dots * 1$$

- for what  $n$  do we know the factorial?

$n = 1 \quad \rightarrow \quad \text{if } n == 1:$   
 $\text{return } 1$  *base case*

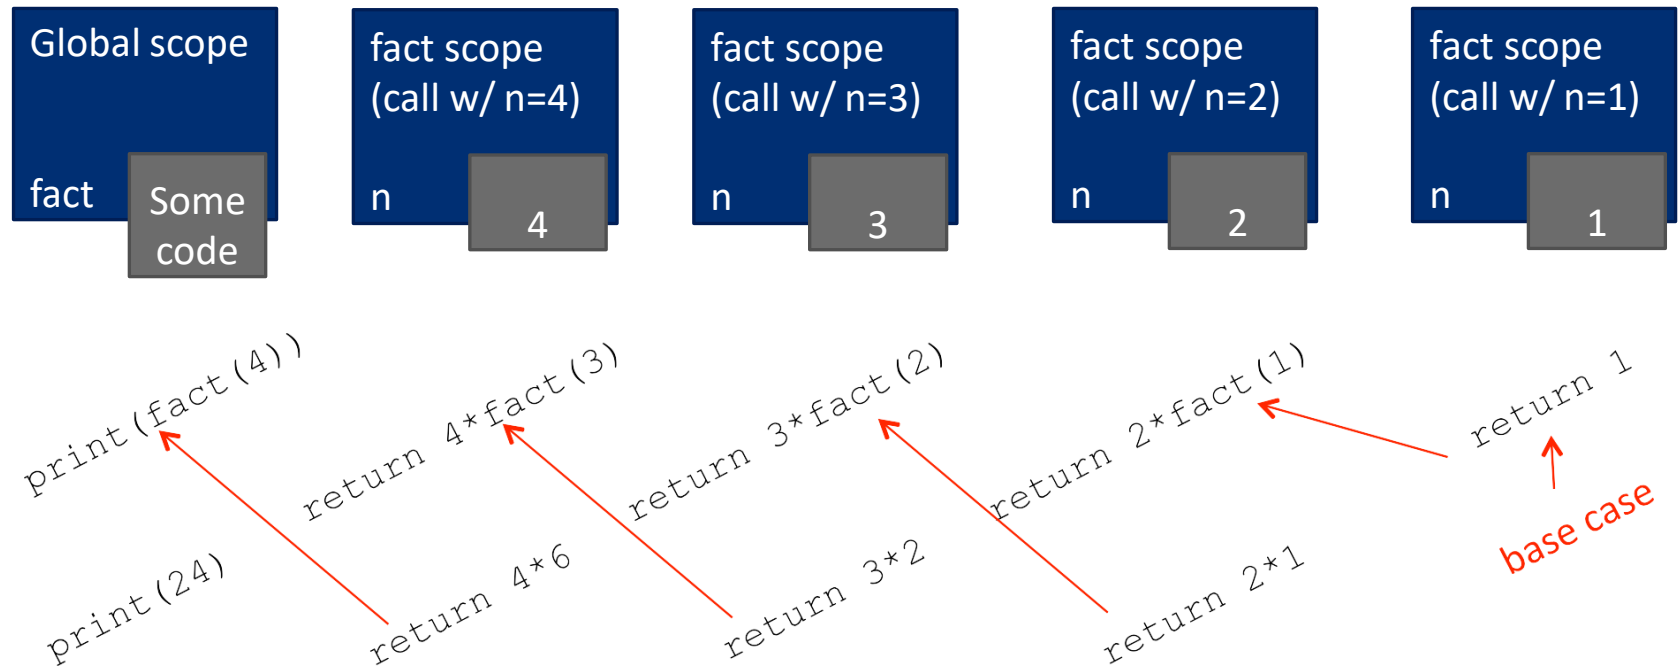

- how to reduce problem? Rewrite in terms of something simpler to reach base case

$n * (n-1)! \quad \rightarrow \quad \text{else:}$   
 $\text{return } n * \text{factorial}(n-1)$

*recursive step*

# RECURSIVE FUNCTION SCOPE EXAMPLE

```
def fact(n):  
    if n == 1:  
        return 1  
    else:  
        return n*fact(n-1)  
  
print(fact(4))
```

# SOME OBSERVATIONS

- each recursive call to a function creates its **own scope/environment**
- **bindings of variables** in a scope are not changed by recursive call
- flow of control passes back to **previous scope** once function call returns value

using the same variable  
names but they are different  
objects in separate scopes

# ITERATION vs. RECURSION

```
def factorial_iter(n):  
    prod = 1  
    for i in range(1,n+1):  
        prod *= i  
  
    return prod
```

```
def factorial(n):  
    if n == 1:  
        return 1  
    else:  
        return n*factorial(n-1)
```

- recursion may be simpler, more intuitive
- recursion may be efficient from programmer POV
- recursion may not be efficient from computer POV

# INDUCTIVE REASONING

- How do we know that our recursive code will work?
- **mult\_iter** terminates because  $b$  is initially positive, and decreases by 1 each time around loop; thus must eventually become less than 1
- **mult** called with  $b = 1$  has no recursive call and stops
- **mult** called with  $b > 1$  makes a recursive call with a smaller version of  $b$ ; must eventually reach call with  $b = 1$

```
def mult_iter(a, b):  
    result = 0  
    while b > 0:  
        result += a  
        b -= 1  
    return result
```

```
def mult(a, b):  
    if b == 1:  
        return a  
    else:  
        return a + mult(a, b-1)
```

# MATHEMATICAL INDUCTION

- To prove a statement indexed on integers is true for all values of  $n$ :
  - Prove it is true when  $n$  is smallest value (e.g.  $n = 0$  or  $n = 1$ )
  - Then prove that if it is true for an arbitrary value of  $n$ , one can show that it must be true for  $n+1$

# EXAMPLE OF INDUCTION

- $0 + 1 + 2 + 3 + \dots + n = (n(n+1))/2$
- **Proof:**
  - If  $n = 0$ , then LHS is 0 and RHS is  $0*1/2 = 0$ , so true
  - Assume true for some  $k$ , then need to show that  $0 + 1 + 2 + \dots + k + (k+1) = ((k+1)(k+2))/2$
  - LHS is  $k(k+1)/2 + (k+1)$  by assumption that property holds for problem of size  $k$
  - This becomes, by algebra,  $((k+1)(k+2))/2$
  - Hence expression holds for all  $n \geq 0$

# RELEVANCE TO CODE?

- Same logic applies

```
def mult(a, b):  
    if b == 1:  
        return a  
    else:  
        return a + mult(a, b-1)
```

- Base case, we can show that `mult` must return correct answer
- For recursive case, we can assume that `mult` correctly returns an answer for problems of size smaller than `b`, then by the addition step, it must also return a correct answer for problem of size `b`
- Thus, by induction, code correctly returns answer

# TOWERS OF HANOI

- The story:
  - 3 tall spikes
  - Stack of 64 different sized discs – start on one spike
  - Need to move stack to second spike (at which point universe ends)
  - Can only move one disc at a time, and a larger disc can never cover up a small disc

# TOWERS OF HANOI

- Having seen a set of examples of different sized stacks, how would you write a program to print out the right set of moves?
- Think recursively!
  - Solve a smaller problem
  - Solve a basic problem
  - Solve a smaller problem

```
def printMove(fr, to):  
    print('move from ' + str(fr) + ' to ' + str(to))  
  
def Towers(n, fr, to, spare):  
    if n == 1:  
        printMove(fr, to)  
    else:  
        Towers(n-1, fr, spare, to)  
        Towers(1, fr, to, spare)  
        Towers(n-1, spare, to, fr)
```

# RECURSION WITH MULTIPLE BASE CASES

- Fibonacci numbers
  - Leonardo of Pisa (aka Fibonacci) modeled the following challenge
    - Newborn pair of rabbits (one female, one male) are put in a pen
    - Rabbits mate at age of one month
    - Rabbits have one month gestation period
    - Assume rabbits never die, that female always produces one new pair (one male, one female) every month from its second month on.
    - How many female rabbits are there at the end of one year?

# FIBONACCI

- After one month (call it 0) – 1 female
- After second month – still 1 female (now pregnant)
- After third month – two females, one pregnant, one not
- In general,  $\text{females}(n) = \text{females}(n-1) + \text{females}(n-2)$ 
  - Every female alive at month  $n-2$  will produce one female in month  $n$ ;
  - These can be added to those alive in month  $n-1$  to get total alive in month  $n$

Month	Females
0	1
1	1
2	2
3	3
4	5
5	8
6	13

# FIBONACCI

- Base cases:
  - Females(0) = 1
  - Females(1) = 1
- Recursive case:
  - Females(n) = Females(n-1) + Females(n-2)

# FIBONACCI

```
def fib(x):  
    """assumes x an int >= 0  
    returns Fibonacci of x"""  
    if x == 0 or x == 1:  
        return 1  
    else:  
        return fib(x-1) + fib(x-2)
```

# RECURSION ON NON- NUMERICS

- how to check if a string of characters is a palindrome, i.e., reads the same forwards and backwards
  - “Able was I, ere I saw Elba” – attributed to Napoleon
  - “Are we not drawn onward, we few, drawn onward to new era?” – attributed to Anne Michaels

# SOLVING RECURSIVELY?

- First, convert the string to just characters, by stripping out punctuation, and converting upper case to lower case
- Then
  - Base case: a string of length 0 or 1 is a palindrome
  - Recursive case:
    - If first character matches last character, then is a palindrome if middle section is a palindrome

# EXAMPLE

- 'Able was I, ere I saw Elba' → 'ablewasiereisawleba'
- `isPalindrome('ablewasiereisawleba')`  
is same as
  - `'a' == 'a'` and  
`isPalindrome('blewasiereisawleb')`

```

def isPalindrome(s):
    def toChars(s):
        s = s.lower()
        ans = ''
        for c in s:
            if c in 'abcdefghijklmnopqrstuvwxyz':
                ans = ans + c
        return ans

    def isPal(s):
        if len(s) <= 1:
            return True
        else:
            return s[0] == s[-1] and isPal(s[1:-1])

    return isPal(toChars(s))

```
